29   512 channel neuronal recording in behaving rodents

30

Abstract

Monitoring representative fractions of neurons from multiple brain circuits in behaving animals is necessary for understanding neuronal computation. Here we describe a system that allows high channel count recordings from a small volume of neuronal tissue using a lightweight signal multiplexing head-stage that permits free behavior of small rodents. The system integrates multi-shank, high-density recording silicon probes, ultra-flexible interconnects and a miniaturized microdrive. These improvements allowed for simultaneous recordings of local field potentials and unit activity from hundreds of sites without confining free movements of the animal. The advantages of large-scale recordings are illustrated by determining the electro-anatomical boundaries of layers and regions in the hippocampus and neocortex and constructing a circuit diagram of functional connections among neurons in real anatomical space. These methods will allow the investigation of circuit operations and behavior-dependent inter-regional interactions for testing hypotheses of neural networks and brain function.

INTRODUCTION

While the exploration of the wiring diagram of brain networks is moving forward at an unprecedented scale (Lichtman and Denk 2011) and steady innovations in optogenetics provide a toolset for identification and manipulation of circuit components (Boyden et al. 2005; Lein et al. 2007; Madisen et al. 2012; Prakash et al. 2012; Tye and Deisseroth 2012; Yizhar et al. 2011), complementary methods for monitoring the activity of large numbers of neurons in multiple local circuits in the behaving animal are lagging (Alivisatos et al. 2013; Buzsaki 2004; Nicolelis et al. 1997). Yet, monitoring a statistically representative fraction of neurons of the investigated circuits in behaving animals is a prerequisite for understanding neuronal computation (Alivisatos et al. 2013; Alivisatos et al. 2012; Buzsaki 2004; Carandini 2012; Nicolelis et al. 1997). Currently, recordings of individual neurons and local field potentials (LFP) in local circuits at high temporal resolution are possible with wire or nano-machined microelectrodes ('silicon probes') (Blanche et al. 2005; Buzsaki 2004; Du et al. 2011; Wilson and McNaughton 1993) (Buzsaki et al. 2012; Logothetis 2003). High-density probes can record from multiple cortical and subcortical structures in the freely behaving animal at the spatial resolution of single neurons (Blanche et al. 2005; Buzsaki 2004; Csicsvari et al. 2003; Du et al. 2011; Fujisawa et al. 2008; Montgomery et al. 2008). Furthermore, silicon probe recordings can be combined with optogenetic methods for the identification of neuron types and selective manipulation of local circuits (Anikeeva et al. 2012; Boyden et al. 2005; Royer et al. 2010; Stark et al. 2012).

While silicon probe technology is poised to offer ever-larger site numbers and smaller volume probes (Du et al. 2011; Du et al. 2009), significant improvements and miniaturization are needed at the level of head-stage interconnects, signal multiplexing, ultra-flexible connection between the animal and the recording equipment, and signal processing (Du et al. 2011; Szuts et al. 2011; Vandecasteele et al. 2012). One critical aspect of miniaturization is the deployment of signal multiplexers. Previously used multiplexers have either low channel counts or limited high- or low-pass frequency characteristics for simultaneous recordings of both unit and LFP signals in the physiological range (Du et al.

3

84   2011; Harrison 2008; Olsson et al. 2005; Szuts et al. 2011; Viventi et al. 2011). Below, we

85   present the development of a high throughput integrated microelectronic system, including

86   high-density, multiple-shank recordings of unit activity and LFP from multiple brain

87   regions, using on-stage signal multiplexing methods. Applications are demonstrated in

88   freely moving rats and mice, including extension to optogenetic manipulations.

89

90   **MATERIALS AND METHODS**

91   *Animal surgery, recording, and behavioral paradigms.* All experiments were approved by

92   the institutional Animal Care and Use Committee of New York University Medical Center,

93   and the Ethical Committee for Animal Research at the Albert Szent-Györgyi Medical and

94   Pharmaceutical Center of the University of Szeged. The experiment protocol was in

95   agreement with the European Communities Council Directive of November 24, 1986

96   (86/609 ECC) and the National Institutes of Health Guidelines for the Care and Use of

97   Animals for Experimental Procedures. Five male Long-Evans rats (400–640 g; 3 to 10

98   months old) were implanted with high-density, 256-site silicon probes under isoflurane

99   anesthesia, as described earlier (Vandecasteele et al. 2012). The probes and the polyimide

100   interconnect cable were manufactured by NeuroNexus, Inc. (http://www.neuronexus.com).

101   In two rats, two probes were implanted; in one rat the probes were placed in the same

102   hemisphere, whereas in the other animal they were placed symmetrically in the two

103   hemispheres (Fig. 1). During surgery, the tips of the shanks are inserted into the superficial

104   cortical layers or approximately 1 mm above the intended subcortical target. After

105   recovery, the probe is moved gradually until the target layer is reached, using 70 to 150 μm

106   rotations per day are made until most or all shanks record units and the probe has reached

107   the desired target. The operated animals were housed in individual cages.

108

109   Neuronal activity in the neocortex and/or the hippocampus was recorded while the animals

110   were running in a 240-cm long linear maze or were performing a delayed alternation task in

111   a similar size T-maze for water reward, or were freely exploring an open field platform.

112   The neuronal activity during rest/sleep in the home cage, preceding and following the

113   waking sessions were also recorded. The wide-band signal was low-pass filtered and down

114 sampled to 1250 Hz to generate the local field potential (LFP) and was high-pass filtered

115 (>0.8 kHz) for spike detection. Malfunctioning recording sites (due to high impedance,

116 cross-talk, short circuit) were removed from the analysis. Operated mice (male, 8-20

117 weeks) were also housed individually after surgery. Details of surgery, optogenetical

118 methods and behavioral tests are available in Stark et al. (2012) (Stark et al. 2012).

119

120 *Histology*. Following the termination of the experiments, the animals were deeply

121 anesthesized, and transcardially perfused first with 0.9% saline solution followed by 4%

122 formaldehyde solution. The brains were sectioned by a Vibratome (Leica, Germany) at 100

123 μm, paralell with the plane of the implanted silicon probes. Sections were DAPI stained and

124 mounted in Fluromount (both Sigma-Aldrich, USA). Some sections were immunostained

125 against calbindin to determine the border between CA3 and CA2. The tracks were typically

126 reconstructed from a few adjacent sections.

127

128 *Single unit analyses*. Extracellular representations of action potentials were extracted from

129 the recorded broad-band signal after high pass filtering (>800 Hz) by a threshold crossing-

130 based algorithm. The dimensionality of the spike waveform representations on 32 contact

131 sites of a given shank were reduced using principal component analysis, and the individual

132 spikes were automatically clustered into groups with the possible lowest internal variance

133 (i.e. representing action potentials generated by single neurons) using KlustaKwik (Harris

134 et al. 2000). The generated cluster groups were manually refined by discarding multiunit

135 clusters showing corrupted autocorrelograms. Groups with unstable firing patterns over

136 time were also deleted. To compare the quality of single unit cluster isolation under various

137 conditions, cluster qualities were estimated using the following two conjunctive measures

138 (Harris et al. 2000; Stark et al. 2012). (1) Cluster overlap in the high dimensional feature

139 space was estimated by the Mahalanobis distance (isolation distance, ID). (2) The ratio

140 between the frequency of spikes present within 0-2 ms interspike interval and those at 0-20

141 ms interval was defined as the interspike-interval ratio (ISI ratio), and used as a measure of

142 possible contamination of an isolated single unit by spikes of another unit. We used two

143 levels of criteria to exclude contaminated clusters from our analyses. In the 'permissive'

144   approach, clusters with either ISI ratio < 0.4 OR ID > 30 were included, while in the

145   'conservative' analyses clusters only with ISI ratio < 0.2 AND ID > 40 were included.

146   The number of simultaneously recorded units (unit-yield) were quantified as an average

147   number of neurons per session per recording site overlapping with cellular layers.

148   For behavior-related analyses, the spatial position of the animal was sampled every 30 ms,

149   with 3 mm resolution. For LFP phase-dependent circular metrics, the phase of each LFP

150   frequency component was determined by Hilbert-transfoming the zero-phase shift digital

151   filtered LFP ($2x4^{th}$ order Butterworth infinite impulse response filter).

152

153   *Cross-correlation analysis.* Monosynaptic interactions of single units were determined by

154   the examination of the cross-correlograms. Short-latency (1-5 ms), narrow (1-2 ms) peaks

155   or troughs (monosynaptic excitation or inhibition, respectively) were deemed significant if

156   they crossed a global threshold band determined from a surrogate dataset of 1000 jittered

157   spike trains (99% confidence interval, ±0-4 ms jittering with uniform distribution;

158   (Fujisawa et al. 2008). For monosynaptic interaction-based network mapping (Fig. 11), the

159   permissive dataset of single units was used, since a moderate contamination of the unit

160   clusters does not introduce spurious short-latency peaks. Spike contamination increases

161   'noise' in the cross-correlogram and, in fact, decreases the probability of finding

162   monosynaptically connected neuron pairs.

163

164   *Spike triggered LFP maps.* Sixty-ms long low-pass filtered (<600 Hz) perispike LFP traces

165   centered at the spikes occurences of the spike-train of selected neurons were extracted. The

166   LFP segments for each recording sites were high pass filtered (20 and 5 Hz for run and

167   sleep sessions, respectively; zero-phase shift $2x4^{th}$ order Butterworth infinite impulse

168   response filter). The purpose of the higher cutoff frequency for run sessions was to

169   eliminate the large amplitude theta fluctuation. The filtered peri-spike segments were

170   averaged across multiple spikes (usually a few thousand occurances for run sessions, and

171   few hundreds for sharp-wave ripple segments). The mean peri-spike LFPs of the 256 or 512

172   recording channels were reordered in 2D to match with the anatomical layout of the

173   recording sites on the silicon probe, forming an activity map of the recorded structures.

174 Consecutive data points in each segment were visualized as multiple frames of a movie,

175 using the following equation:

$$MAP_{ij} = \frac{\tan^{-1}\left(\frac{LFP_{ij}}{\max LFP} * zf\right)}{\tan^{-1}(zf)}, \qquad i \in N\{1, ...,8\}, \qquad j \in N\{1, ...,32\}$$

176 where MAP_{ij} is the transformed activity value of the ith shank and j^{th} contact site to be

177 displayed, LFP_{ij} is the filtered mean LFP value of a given channel, and zf is an arbitrary

178 zooming factor. This transformation helped to visualize the smooth activity patterns while

179 relatively suppressing the gross changes. The generated activity-map (heatmap) frames

180 were further smoothed in space by cubic spline interpolation (10x upsampling), and in time

181 by a 150 µs (three sample) wide moving average filter. A schematic of the anatomical

182 layers was overlayed on each frame, based on the histological verification of electrode

183 location.

184

185 *Mapping high frequency power.* The LFP signals were filtered by a narrow gaussian band-

186 pass filter (peaks at 300 Hz, SD = 10 Hz) and the power was summed up for 1-second-long

187 periods. Several other high-passed signal bands (>300 Hz) provided similar results. In the

188 hippocampus, the selected periods typically contained a sharp wave ripple event to

189 maximize the presence of unit firing since the goal was to identify the somatic layers.

190 Several other frequency bands and bandwidths were tested and the 300 Hz band was found

191 empirically the most effective to outline the cell body layers (Ray and Maunsell 2011). This

192 band was also less sensitive than higher frequencies due to the wide amplitude range of the

193 isolated units that vary from site to site. The high frequency power distribution effectively

194 outlined the CA1 and CA3 pyramidal layers and the dentate area. In addition, the high

195 frequency power map agreed well with the locations of the clustered neurons. The predicted

196 positions of the cell body layers were in good agreement with the anatomically

197 reconstructed tracks of the probe shanks.

198

199 *Coherence analysis.* Using coherence as similarity measure, an interaction-energy based

200 clustering was implemented to identify cell layers. Every site served as a reference against

201   all the other referred sites. The resulting values were clustered using a gradient-descent
202   algorithm, so that each site was merged with that cluster for which the resulting coherence
203   gain after merging was the largest. Starting from random initial assignments, the clustering
204   algorithm formed stable but fewer clusters corresponding to a local energy minimum.
205   Energy of cluster A is defined as:

$$E^A = \frac{-1}{N^A} \sum_{i,j \in A} C_{ij}$$

206   Where, C_{ij} is the coherence between i^{th} and j^{th} sites and NA is the number of recording sites
207   in cluster A. The energy gap between two different assignments to cluster A and B of site i
208   is:

$$E^A = \frac{-1}{N^A} \sum_{i,j \in A} C_{ij}$$

209   If the energy gap is positive, site i is moved into cluster B, otherwise it remains in cluster
210   A. Since the method results only local minima of energy and stochastic components, such
211   as the random initial condition and update order affects, clustering consistency was verified
212   by repeating the process several times. Small (less than 3 sites in a cluster) and scattered
213   clusters (typically representing bad channels) were deleted and their sites were included
214   into the majority cluster of their immediate neighborhood. This clarification was done
215   either before and after merging the coherence clusters and MUA map. The resulting
216   clusters effectively differentiated the different anatomical layers of the hippocampus (Fig.
217   5). The same coherence similarity method was used in the neocortex to differentiate the
218   superficial, middle (layer IV) and deep layers of the neocortex (Fig. 8).
219
220   *Merging the MUA and coherence cluster maps.* MUA map was thresholded at 70% of its
221   maximum to define the cellular layers (CA1 and CA3 pyramidal and DG granular). These
222   sites were deleted from the coherence clusters to define new clusters. As a result, the CA1
223   and CA3 pyramidal layer and the granular layer became different clusters, designated as
224   cell body layer clusters.
225
226   *Coastline display.* In a different display, each site was connected to the most coherent sites

227 on the neighboring shanks, which connected forward to the most coherent site of the next

228 shank, and so on. The recording positions were slightly and randomly scattered, to assist

229 visualizing the different lines crossing the same points. The connecting lines were colored

230 on the basis of the cluster identity of their seed.

231

232 *Estimation of recording quality and comparison to a commercially available non-*

233 *multiplexing recording system.* In order to obtain an objective measure of the recording

234 quality of our multiplexing system, we performed the following analyses. The input-

235 referred noise of the recording channels was measured by short circuiting all inputs of the

236 INTAN chip to the reference channel. The power spectrum of a ten second-long recording

237 was whitened after performing Fourier transformation. To evaluate the quality of recorded

238 LFP and units, several consecutive, ten-minute long sessions (typically during immobility

239 and sleep) were recorded from the hippocampus with a Buzsaki32 four-shank silicon probe

240 (NeuroNexus Inc.). The recordings were made with either our multiplexed system (test) or

241 a commercially available non-multiplexed system (control) in an alternating sequence. The

242 control system consisted of a headstage (gain=20x; HST/32V-G20; Plexon Inc, Dallas, TX,

243 USA), connected by a 40-wire Litz cable (same length as in the multiplexer's cable) to a

244 Digital Lynx 16SX A/D converter (Neuralynx, Bozeman, MT, USA). The multiplexed

245 signals were sampled at 20 kS/s, while the Digital Lynx used 32 kS/s sampling. Pearson's

246 linear correlation was calculated across all combination of channels (496 pairs), and

247 visualized as a correlation matrix. A mean correlation value of the entire 10-minute long

248 recording was calculated for channels on the same shank (within-shank correlation), and for

249 channels located on different shanks (across-shank correlation). To estimate the

250 contribution of higher frequency components in the correlation, we repeated the analysis

251 twice after passing the signals through a low-pass 4th order Butterworth zero-phase lag

252 digital filter (arbitrarily chosen 10 Hz and 100 Hz cutoff frequencies, respectively). The

253 raw recorded signals were processed to extract single unit spike trains, and clustered

254 automatically by the KlustaKwik program (Harris et al. 2000). To avoid subjectivity, the

255 manual cluster refinement step was limited to eliminate the obvious noise clusters

256 (waveforms with same amplitude and shape on every recording sites of the given shank).

257 The number and quality of the isolated single units were assessed using the following three
258 criteria. In the first analysis, the number of automatically isolated non-noise clusters were
259 compared, disregarding their isolation quality. In the second comparison, we measured the
260 ratio of the number of isolated spikes and the number of 'noise' waveforms to estimate the
261 signal to noise ratio. Third, we used two levels of cluster quality measures ('permissive'
262 and 'conservative'; see above). The recorded waveforms of identical spike clusters
263 recorded by the two systems were also compared after amplitude normalization, and offline
264 interpolation (upsampling) to 50 kS/s.

265
266 **RESULTS**
267 **System Description**
268 Large-scale recordings from multiple single units, large spatial coverage and limited tissue
269 displacement/damage by the electrodes are competing conditions (Buzsaki 2004; Du et al.
270 2011). Our goal was to monitor single unit and LFP activity patterns of neighboring
271 neocortical regions and interconnected hippocampal subregions. To this end, we designed
272 an 8-shank probe with 32 recording sites on each shank (Fig. 1A). The recording sites are
273 arranged vertically at 50-µm steps, providing sufficient spatial resolution for unit clustering
274 (Csicsvari et al. 2003; Montgomery et al. 2008; Wilson and McNaughton 1993), yet large
275 vertical coverage (1550 µm). Each recording site is 165 µm^2 and has an impedance
276 between 1.3 to 3 Mohms. The shanks are placed 300 µm apart to eliminate simultaneous
277 recording of neurons by adjacent shanks (Henze et al. 2000) and provide spatial coverage
278 of adjacent neocortical modules or hippocampal regions (Csicsvari et al. 2003). Each shank
279 is 15 µm thick, and tapered from a sharp tip to 96 µm at the uppermost recording site to
280 minimize tissue damage, yet rigid enough to allow smooth penetration through brain tissue.
281 The total volume of the probe shank, containing the recording sites, is comparable to a
282 traditional wire tetrodes (Wilson and McNaughton 1993). In contrast to the blunt tetrode,
283 which often tears intracortical blood vessels during penetration, the tapered profile of the
284 silicon probe shanks allows it to be moved up and down in the brain with continued yield of
285 units. The probe is connected to a microdrive so that the probe sites can be advanced to the
286 vicinity of the desired neurons (Vandecasteele et al. 2012) (Fig. 2).

10

288 *Signal multiplexing and processing*

289 A major challenge of the effective use of silicon probes in small animals is to reduce the

290 volume and weight of the instrumentation between the probe and the recording equipment.

291 Multiple connectors, traditional preamplifiers and multi-strand cables for each recording

292 site are not viable for high-density probes; the large volume and weight of these

293 components and the increased tension of the connecting cable significantly limit the

294 behavior of the small rodent. In addition, using large numbers of individual external

295 amplifiers is prohibitively costly and involves complex cabling. A logical solution to these

296 problems is the deployment of time-division multiplexing (Harrison 2008; Olsson et al.

297 2005; Szuts et al. 2011; Viventi et al. 2011). To this end, we used 32-channel VLSI analog

298 signal multiplexers developed specifically for brain recording applications (Harrison 2008)

299 (RHA2132, INTAN Inc., www.intantech.com). Eight multiplexers are soldered to a

300 custom-designed printed circuit board, four on each side (Fig. 1A), to transmit a total

301 number of 256 channels. To allow movement of the probe, and preserve its small inertia an

302 ultra-flexible polyimide-based cable was designed and served as an interconnect between

303 the probe and the multiplexing headstage (Fig. 1A).

305 Each of the 256 electrical signals acquired by the silicon probe is amplified and band-pass

306 filtered (gain = 200x, cutoff frequencies of the high-pass and low-pass filters are 0.3 Hz, -6

307 dB/octave and 10 kHz, -18 dB/octave, respectively) (Fig 1B). The broadly tuned cutoff

308 frequencies allow the recording of broad-band signals (LFP and unit activity

309 simultaneously) from all recording sites. The signal multiplexer chips were programmed to

310 switch sequentially between channels every 1.5 µs, so that a sweep of 32 channels

311 corresponds to 48 µs (Fig 1C, D). To accomplish a 50-µs cycle length (20 complete scan

312 cycles in a millisecond), the last channel of the 32-channel block was transmitted for two

313 more microseconds before looping back to the first channel of the subsequent cycle. The

314 post-loop 2µs time was used to protect against desynchronization of the multiplexing

315 sequence. Potential desynchronization of the multiplexing and demultiplexing sequence

316 may occur if the clock signal accidentally advances the sequence of the multiplexed signal.

317   Such accidental 'jumps' are avoided by resetting the binary counters to zero (binary code

318   00000) during the 2-μs post-loop time. This clock supervision mechanism ensured that

319   even if the clock code is corrupted for any reason, only one sample is misplaced in the

320   sequence of the parallel-decoded channels. To reduce the wiring complexity of the printed

321   circuit board interconnects, the 32 recording sites of a given shank did not correspond to a

322   single multiplexer but were distributed among at least four chips. This had the added value

323   that in case of a chip failure some recordings from all shanks remained available.

324

325   We found that the relatively high output impedance of the RHA-2132 multiplexer chip was

326   not sufficient to reliably transmit signals over long data cables (over 5 meters), typically

327   needed in behaving experiments. To improve signal settling time and to circumvent the

328   capacitive load of the cable, high precision operation amplifiers (MCP622; Microchip,

329   USA; slew rate: 27 V/μs; Fig. 3D) were added in series to buffer the multiplexed signals.

330   With the added buffering, the signal settled in less than 100 ns to 1% precision after each

331   switch of the multiplexer chip even when up to 15 meter-long cable, consisting of 36-gauge

332   (110 μm) Litz wires, was used. The ultra-light and ultra-flexible cable allowed for a free

333   movement of the animal (Vandecasteele et al. 2012) (Fig. 2F).

334

335   To achieve synchronous channel advancement on every multiplexer chip without adding

336   further weight and surface area to the head stage, the common clock signal (640 kHz, 50%

337   duty cycle) is generated by a programmable integrated circuit in the external controller box

338   ('main box'). A five-bit binary clock code was generated by a synchronous binary counter

339   (74HC163; Texas Instruments, USA) on the head stage to address the channels of the

340   multiplexers within blocks of 32. In the main box, the multiplexed signals were further

341   amplified (gain = 2, total gain = 400), and their baseline was corrected by the subtraction of

342   a preset DC value. The multiplexed signals (Fig. 1C, D) were sampled by a high-speed

343   digital-to-analog converter (PCI-6133; National Instruments, USA). Sampling was initiated

344   by the mainbox's clock generator microchip 125 ns prior to the subsequent channel switch

345   to maximally exploit the available signal settling time.

346

347   *Software control*

348   To generate the clock and trigger signals, the programmable integrated circuit was activated

349   by the recording software only after the digital-analog data acquisition (daq) task was

350   properly set up, and was idle for the external trigger to start sampling. The recording

351   software program acquired samples from the buffer in chunks of 100 ms (100 ms x 20

352   samples per ms x 32 channel= 64000 samples per multiplexed line). This 100 ms (10 Hz)

353   readout frequency offered a practical compromise between minimizing the time

354   requirement introduced by the frequent updates of the processing code headers, yet

355   provided a smooth, real-time-like data display on the computer screen. After the buffer has

356   been filled, the acquired data was read out by the recording software and was reordered to a

357   32 x 2000 size matrix. The synchronous initiation of the sampling and clock advancement

358   ensured that the dataset of each buffer readout started with a sample corresponding to the

359   first channel on the input side of the multiplexer chip (Fig. 1D). Although the actual clock

360   code of the software and the hardware was not synchronized after the initiation, we never

361   experienced any misalignment of the channel order even after extended testing of the entire

362   system up to 40 kS/s sampling speed per channel. The electrophysiological recording setup

363   was combined with a universal serial bus (USB) web camera recording system for the

364   continuous monitoring of the animal's position and behavior (Figures 2 and 3).

365

366   *Real time hardware demultiplexing*

367   Many applications need not only recording of the neuronal signal but also its real time

368   availability, e.g., to interact with brain circuits in close-loop experiments (Berenyi et al.

369   2012; Stark et al. 2012). However, the content of the buffer of the analog-digital card is

370   read only once every 100 ms, and the software routines introduced between an analog-

371   digital and digital-analog conversion *per se* provide a suboptimal time precision for brain

372   feedback stimulation. To achieve real-time readout (<50 μs per sample), we designed a

373   mixed analog/digital demultiplexing device (Fig. 4). The demultiplexer, in addition to

374   receiving analog data streams, was timed by the same clock signal that drove the head

375   stages, and the rest of the clock bits were generated by the principle as described above for

376   the multiplexers. Two separate bit-masks (two-bit and three-bit) were generated by a

13

377 microcontroller-driven user interface that allowed the selection of any one of the eight

378 multiplexed streams (using an analog switch circuit), and any of the desired channels of the

379 selected stream (one of 32). Demultiplexing was established by a pattern matching

380 algorithm: the real five-bit clock signal was compared to the user preset clock bit mask by a

381 series of XNOR and AND logic gates. The digital output of the circuit generated a digital

382 high level only if the clock mask matched the real clock signal (i.e., approximately the

383 duration of the desired channel's segment within the multiplexed stream). In principle, this

384 digital pulse was suitable to trigger the sampling mode (i.e., a voltage follower) of a

385 sample-and-hold integrated circuit, which worked as a voltage follower. The falling edge of

386 the trigger pulse switched the sample-and-hold circuit to hold the last voltage value until

387 the next sampling cycle, thus bridging the time gap while the consecutive channels were

388 transmitted in the multiplexer line (Fig. 4A). Because the propagation time of the digital

389 gates introduced a significant delay in the digital trigger pulse, it could not be used directly

390 to trigger the sample-and-hold circuit. To correct for the delay, a monostable multivibrator

391 ('one shot') was used to generate a shorter pulse (1.3 µs) so that the sampling was

392 terminated before switching to the subsequent sample in the multiplexer line. The output of

393 the sample-and-hold circuit was then low-pass filtered (at 10 kHz) to eliminate the step

394 responses (Fig. 4B). The reconstructed analog signal was amplified or filtered further as

395 required for audio-monitoring the recorded signal or viewing the waveform on an

396 oscilloscope (0.5 Hz-5 kHz; Fig. 4D and E).

397

398 *Physical dimensions*

399 To eliminate complex cabling and connections of high-channel counts of the probe, the

400 probe was permanently connected to the 256-channel multiplexer headstage (4.7 grams; 34

401 mm x 39 mm x 2.5 mm) and is worn chronically by the rat. During recording, the animal

402 was connected to the recording system through an ultraflexible cable (Vandecasteele et al.

403 2012) (twelve 127 µm diameter insulated copper wires, 455 µm total diameter cable; Fig.

404 2F). For recording from smaller size silicon probes or tetrodes targeting multiple brain

405 structures, we constructed 32- and 64-channel versions of the multiplexer headstage (32

406 channel 0.9 gram; 13 mm x 15 mm x 3 mm; 64 channel: 1.2 gram; 13 mm x 19 mm x 3

407 mm, respectively; Fig. 3). In contrast to the 256-channel version, the front ends of these

408 headstages were connected to the probe output by high-density connectors (Omnetics, Inc.)

409 during the experiments.

410

411 *Validation of the recording system and estimation of the signal quality*

412 We estimated the mean input referred noise spectrum for all channels of the 32-channel

413 multiplexer headstage (the results presented here applies to the 64- and 256-channel

414 headstages as well, since they consists of parallel-connected 32-channel blocks). When the

415 input channels were short-circuited with the reference pin of the headstage, the mean RMS

416 amplitude of 60 Hz noise was 7.2 µV (range = 2 - 8.5 µV), which is approximately one

417 order of magnitude higher than the ½ least significant bit of the A/D conversion. We also

418 compared the signal quality to a commercially available recording system (HST/32V-G20

419 pramplifier (Plexon Inc, Dallas, TX, USA) and Digital Lynx 16SX A/D converter

420 (NeuraLynx Inc, Bozeman, MT, USA). The amplitude of the signal was approximately

421 20% smaller using the INTAN amplifier chips than that of the non-multiplexing control

422 system, which can be explained by the lower input impedance of these chips. However, the

423 signal waveforms and the wave shapes of the extracellular spikes were virtually identical.

424 The mean difference between the normalized spike waveforms of a well-isolated test single

425 unit, recorded by the current and the control system, was 10% of the standard deviation of

426 the waveform recorded by the control system. The common noise component across

427 channels in the recorded LFPs was significantly lower, especially in the lower frequency

428 ranges, which is presumably a result of the serial transmission of the channels in the

429 multiplexed line instead of the non-multiplexed parallel transmission. The intra-shank

430 correlation of the recorded signals (i.e., the mean of the correlation values calculated

431 between pairs located on the same shanks; see MATERIALS AND METHODS) was

432 similar in both systems for every investigated frequency range. However, the mean

433 correlation across the shanks gradually decreased at higher frequencies in our system

434 (R=0.8, 0.72 and 0.23 for >1, >10, and >100 Hz respectively), while slightly increased for

435 the control system (R=0.55, 0.72, 0.75). The single unit yield was larger in our system,

436 despite the slightly lower signal amplitude, and lower sampling rate (20 kS/s vs. 34 kS/s).

437   After the automatic spike extraction and clustering of the sample session recorded by both

438   systems (see MATERIALS AND METHODS), 26 and 7 single units were detected on a

439   single shank, using our (test) and the control systems, respectively. After taking account of

440   cluster quality criteria, nine vs five clusters, respectively, satisfied our 'conservative'

441   criteria (see MATERIALS AND METHODS).

442

443   **Physiological Recordings**

444   *Electro-anatomy of cortical layers*

445   We have implanted the high-density, 256-site probes in 5 rats. In two rats, two probes were

446   implanted (512 channels). In one rat the probes were placed in the same hemisphere,

447   whereas in the other animal they were placed symmetrically in the two hemispheres (Fig.

448   2).

449

450   The relationship between laminar arrangement of afferents and the characteristic depth

451   profiles of various oscillatory and irregular LFP patterns can offer means for an

452   identification of the various cortical layers and their transitions (Buzsaki et al. 2012;

453   Montgomery et al. 2008). Here we illustrate our strategy in the hippocampus, whose

454   laminar structures and well-understood LFP patterns allow for an online quantitative

455   identification of each of the recording electrode sites (Montgomery et al. 2008).

456

457   First, each of the 256 LFP signals were filtered by a narrow gaussian band-pass filter (peak

458   = 300 Hz, SD = 10 Hz) and power values, determined from a randomly sampled 1-sec

459   epoch, are displayed for each of the 256 sites as a 2-dimensional map (Fig. 5A). This

460   frequency band was empirically determined by selecting a frequency band with the largest

461   ratio of power between cell body layers and dendritic layers (Fig. 6). The band we selected

462   (300 Hz Gaussian filter, SD = 10 Hz) presumably represents various aspects of multi-unit

463   activity (Ray and Maunsell 2011), since its spatial distribution clearly marked the

464   pyramidal layer and the dentate-hilar area, as reflected by the density of the recorded units.

465   The soma location of the recorded neurons was estimated by the largest amplitude

466   waveform representing the firing of each unit (Csicsvari et al. 2003; Fujisawa et al. 2008)

467 and assigned to the recording site of the relevant shank in the electro-anatomical map (Fig.

468 5A). In the next step, coherence maps in the gamma frequency band (40-90 Hz) were

469 constructed. Each site served as a reference and coherence distribution with each of the

470 remaining 255 sites was determined iteratively (Montgomery et al. 2008) (Fig. 5B and 7A).

471 Using a gradient-descent algorithm (Fig. 7), the recording sites were clustered based on the

472 resulting coherence matrix, and the resulting coherent channels were grouped together.

473 Next, a two-dimensional gamma coherence map was generated (based on the spatial

474 locations of the recording sites and their coherence cluster identities) and combined with

475 the power map (Fig. 5C) to identify the cellular layer amongst the emerging clusters. The

476 boundaries of the channel clusters happened to be nicely overlapping with the anatomical

477 layers without any *a priori* knowledge of the histological control. In a different display,

478 each recording site was connected to its most coherent neighbor on the adjacent shanks.

479 The connecting lines were colored-coded on the basis of cluster identity of their leftmost

480 member site. The resulting 'coast-line' display provided a smooth layer-specific map of the

481 recorded space by the silicon probe (Fig. 5C, right). The electro-anatomical map

482 constructed from unit firing and LFP signals corresponded faithfully to the histological

483 reconstruction of the electrode tracks and the anatomical layers of the hippocampus (Fig.

484 5D).

485 High-density silicon probe recordings in the neocortex were similarly advantageous for

486 cortical layer identification. Gamma coherence reliably identified three separate layers,

487 corresponding to the superficial (II/III), middle (IV) and deep (V/VI) layers (Fig. 8A).

488

489 *Large-scale recording of unit activity*

490 Figure 8B shows wide-band (0.5 Hz – 10 kHz) traces from a single shank in the

491 somatosensory cortex. Neurons were recorded from all shanks of the probes in both

492 hemispheres for several days before advancing the probes into the hippocampus. In

493 conjunction with LFP, population patterns of unit firing allowed for a clear classification of

494 brain states (Fig. 8C).

495 Neocortical and hippocampal units were clustered semi-automatically (Harris et al. 2000),

496 followed by physiological classification of the units into putative principal cells and

17

497   interneurons (Bartho et al. 2004; Fujisawa et al. 2008). To obtain an 'at glance' information

498   about the recorded neurons, an algorithm was designed to summarize the main

499   physiological and behavioral correlates of each unit (Fig. 9). First, the mean waveform of

500   the unit recorded at multiple sites is displayed, together with wave shape classification of

501   the unit, and its autocorrelogram and interspike interval histogram. The next level of

502   analysis characterizes the spike-LFP relationships. In case of hippocampal neurons, the

503   preferred firing phase in relation to theta, gamma and ripple oscillations of the unit are

504   displayed, together with sharp-wave related firing (Fig. 9). The third level of analysis

505   shows the neurons' behavioral correlates, such as its place related firing in the maze and

506   spike phase precession relative to the theta rhythm (Fig. 9). The display panels can be

507   flexibly replaced with other analyses, such as displaying the anatomical location of the

508   neuron in two-dimensional space, its cluster space relative to surrounding clusters, brain

509   state-dependence of firing rates and cross-correlation with selected other neurons.

510

511   The 256-site probe was designed for large spatial coverage to allow monitoring the activity

512   in multiple hippocampal layers. This inevitably compromised the density of the recording

513   sites (50 μm) and, consequently, reduced the unit clusters with high isolation quality

514   (MATERIALS AND METHODS) compared to higher density (20 μm spacing) probes.

515   However, the lower unit yield per site was offset by the 256-site probe's ability to record

516   from multiple layers (Fig. 10)

517

518   Large-scale recording from local circuits has the power of identifying monosynaptic

519   connections, at least between principal cells and interneurons (Fujisawa et al. 2008). This is

520   typically done by examining counts of co-occurrences of spiking in the putative pre- and

521   postsynaptic neurons, as exemplified by the large peaks at short latency time lags (Fig.

522   11A, B). Our analysis is limited only to pyramidal-interneuron interactions, since the

523   validation of the monosynaptic peaks on the cross-correlograms of the pyramidal-pyramidal

524   neurons pairs was not reliable due to their low firing rates. However, with extended

525   recordings and increased number of spikes, the circuit analysis can be extended to

526   pyramidal-pyramidal connections as well (Hirabayashi et al. 2013). Of the 26,406 possible

18

527 connections of a total of 163 simultaneously recorded neurons (counting each literal pair

528 twice, corresponding to the two directions) recorded by two probes (512 sites) in the same

529 hippocampus (Figure 11A, B), 137 pairs (0.005%; marked red in Fig. 11C) had short

530 latency (<5 ms onset) and narrow significant peaks (<2 ms) or troughs in their cross-

531 correlograms, indicating that the presynaptic partner neuron was an excitatory or inhibitory

532 neuron, respectively. In most cases, the postsynaptic targets were interneurons, as judged

533 by their high firing rates and waveforms (Sirota et al. 2008). Most functionally connected

534 pairs were detected locally in the same hippocampal region but several connections were

535 detected between neurons in the CA3 and CA1 regions as well (Fig. 11). Several pyramidal

536 cells of both local and distant origin could converge on the same putative interneuron.

537

538 Increasingly larger numbers of simultaneously recorded neurons also facilitates the search

539 for spatiotemporal patterns of neuron interactions in local circuits because the likelihood of

540 finding connected pairs increases quadratically with the number of the recorded cells

541 (Bartho et al. 2004; Carandini 2012). Since the spike transmission probability (i.e., the

542 excess numbers of postsynaptic spikes divided by the number of presynaptic spikes,

543 reflecting the efficacy of spike transfer function) can be used as an indirect measure of

544 synaptic strengths between neurons (Fujisawa et al. 2008), the magnitude of spike transfer

545 can be used in future studies to estimate the state and task-related circuit reconfigurations

546 (Fujisawa et al. 2008).

547

548 *State-dependent activation of single neurons by multiple inputs*

549 In the intact brain, neurons are embedded in interconnected networks and respond with

550 spikes to a single input or a combination of inputs. Since afferents to hippocampal neurons

551 target specific layers, high-density recordings from multiple layers and regions can, in

552 principle, track the activity of the afferents giving rise to each spike. To illustrate the

553 principle, we sampled LFP multiple times at all recording sites in 20-msec windows,

554 centered on the spikes of a CA1 pyramidal neuron during sharp wave-ripple events and

555 ambulation while the rat was walking through the place field of the neuron (O'Keefe and

556 Nadel 1978) (Fig. 12; Supplemental movie 1). Sharp wave-ripples are self-organized

557 population patterns that arise in the CA3 region and depolarize the mid-apical dendrites of

558 CA1 neurons, as seen extracellularly by a large amplitude negative wave in stratum

559 radiatum (Ylinen et al. 1995). As expected, LFP activity prior to the occurrence of spikes

560 during sharp wave-ripple events was most prominent in the CA1 stratum radiatum (Fig.

561 12A; Supplemental movie 1). In contrast, during place-related activity pyramidal cells are

562 believed to be discharged by a combination of the direct entorhinal input terminating in

563 stratum lacunosum-moleculare and the CA3 input (Moser et al. 2008) (Fig. 12B). During

564 ambulation, LFP activity prior to spike occurrence was first observed in the stratum

565 lacunosum-moleculare and dentate molecular layer, followed by the CA3 activation in CA1

566 stratum radiatum prior to the spikes of the place cell. These findings illustrate the

567 exceptional power of the combination of recording spikes and high spatial density

568 monitoring of LFP for understanding the input-output transformation of single neurons.

569

570 *Large-scale recordings from the mouse brain*

571 Multiplexing neuronal signals is even more critical for recordings from mice because the

572 size and weight of the preamplifiers and the connecting cable can seriously affect the

573 behavioral performance of the animal. Either 32-channel or 64-channel head stages and

574 their combinations are deployed for high-density recordings from two or three brain

575 structures, including various neocortical areas, hippocampus, thalamus, nucleus accumbens

576 and ventral tegmental area. In addition to the multiplexed outputs, the recording head stage

577 contains two detachable LEDs for tracking the animal's position with a video camera and a

578 3-dimensional accelerometer to monitor fast head movements. Figure 13A shows

579 illustrative neocortical traces from a mouse exploring an open maze. The silicon probe

580 recordings are most often combined with optogenetic manipulation of the recorded neurons,

581 using laser or LED-powered sharpened optical fibers that deliver light to the tips of the

582 probe shanks (Berenyi et al. 2012; Royer et al. 2010; Stark et al. 2012) (Fig. 13B).

583

584 **DISCUSSION**

585 We have described a complete system that allows high channel count recordings from a

586   small volume of neuronal tissue using a lightweight signal multiplexing head-stage that

587   permits free behavior, such as exploration in mazes. This was achieved by multiple stages

588   of development, including multishank high-density recording silicon probes, ultra-flexible

589   interconnect, miniaturized microdrive (Vandecasteele et al. 2012) and, most importantly,

590   high throughput on-stage signal multiplexing, remote-site digitization and demultiplexing,

591   which allow to link the animal to the recording/processing hardware by an ultra-light cable.

592   The system has been extensively tested for large-scale recordings of spike outputs and LFP

593   signals in both rats and mice. The two-dimensional distribution of the recording sites

594   distributed across several layers and regions can provide important information about the

595   distribution of LFP together with large-scale unit recordings

596   Sensing of electrical activity is complementary to optics-based imaging methods

597   (Alivisatos et al. 2013). Silicon probes can access deep brain structures and offer sampling

598   speed at the level of neuronal communication. They provide neuron-scale resolution in

599   local circuits and permit the study of interactions of multiple brain regions, currently not

600   practical with imaging methods (Ghosh et al. 2011). Electrodes are invasive, a feature that

601   can be improved with further size reduction, refinement of tip configuration and tissue

602   compatible coating (Du et al. 2011; Kipke et al. 2008; Wise et al. 2004). In the current

603   configuration, the combined volume of the eight recording shanks of the 256-site probe is

604   comparable to the volume of eight wire tetrodes (Wilson and McNaughton 1993) but it can

605   record from significantly larger numbers of units in addition to providing high-spatial

606   resolution LFP signals. Even the eight-shank 64-site probe can record from >100 neurons

607   (Fujisawa et al. 2008). In addition, linear probes have the advantage of online identification

608   of the recording layers, the spatial localization of the main current sources and sinks and the

609   positions of the recorded neurons (Csicsvari et al. 2003). We present here a method to

610   determine the position of the electrodes during experiments, exploiting the high within-

611   layer gamma band coherence of the LFP. Polarity reversal of sleep spindles, K complexes

612   and other LFP patterns can also be used to increase the precision of layer segregation. Since

613   the layer identification we described is done in situ, it allows for the determination of the

614   recordings sites in each session. This is a major advantage in experiments when the probe is

615   moved gradually in the course of multiple sessions and for layer-restricted optical

616   stimulation in future experiments.

617   The 50-µm spacing of the recording sites on the 256-site probe (Fig. 1A and Fig. 10.) is

618   suboptimal for unit recordings and cell clustering (Harris et al. 2000). Denser recording

619   sites without increasing the shank volume is desirable. On the other hand, the additional

620   two-dimensional recording of the LFP from multiple layers and regions is an additional

621   benefit. Due to the rapid development of silicon technology, probes with >1000 site counts

622   and 20 µm site spacing, yet without further size increase, are expected in the near future.

623   Ultimately, a dynamically reshapeable probe design (by selecting recording sites within the

624   cellular layers with high quality unit activity) would overcome the tradeoff of the current

625   probe design, by significantly improving the single unit yield and still keeping the amount

626   of recorded data reasonable at the same time.

627

628   In addition to significantly increasing the number of recording sites, the size of the

629   multiplexers should also be considerably reduced. Although the size and weight of the

630   extracranial devices is less of a problem in head-fixed animals, currently they are the most

631   limiting factors in experiments that require free movement of small rodents. In the current

632   configuration, silicon probes are connected to the multiplexers via an ultraflexible

633   polyimide cable but the multiplexers have to be manually soldered onto the printed circuit

634   board. In addition to size limitation, the numerous mechanical connections between the

635   probe, interconnect, multiplexers and the offsite demultiplexer increase failure rate.

636   In terms of the cluster quality of units, our system outperformed a benchmark commercial

637   recording system. The relatively low input impedance of the INTAN RHA-2132

638   multiplexer chip (13 MΩ at 1 kHz) and its relatively high input capacitance (12 pF)

639   attenuated the recorded signal by approximately 20%, comparing with another non-

640   mulitplexed headstage. However the serial, temporally non-coincident transmission of the

641   mutliple channel segments make the multiplexer more resistant to mechanical cable

642   artifacts. Signal attenuation of the multiplexer could be eliminated by adding buffer

643   operational amplifiers before multiplexing. However, such modification may double the

644   current size of the multiplexer, adding unwanted additional weight and volume to the
645   headstage.

646

647   New generation probes may have on-probe signal amplification and multiplexing
648   capabilities (Csicsvari et al. 2003; Olsson et al. 2005). Alternatively, the required signal
649   multiplexing circuits can become an integral part of the flexible interconnect cable (Viventi
650   et al. 2011). The use of flexible and active interface electronics may offer an alternative
651   approach that may be advantageous for several applications. The digital output of the
652   multiplexers (Harrison 2008) allows direct streaming of the neurophysiological data to the
653   computer without the extra step of analog-digital conversion. Digital multiplexers also offer
654   noise reduction since potential noise sources of cable transmission, further amplification
655   and offsite digital conversion can be eliminated (Harrison 2008). In principle, amplification
656   and multiplexing can be placed on the probe shanks, effectively reducing the required large
657   numbers of interconnects between the recording sites and electronics outside the brain.
658   Unfortunately, current CMOS circuits require ~ 1 V supply voltage and may generate both
659   excess heat and local electric fields that may modify the activity of nearby neurons if
660   placed on the shank itself (Berenyi et al. 2012). Thus, without dramatic reduction the power
661   consumption , brain embedded electronics remains a major challenge (Alivisatos et al.
662   2013).

663

664   In principle, cables interconnecting the head stage and the recording system can be
665   completely eliminated by telemetry. While up to 64-channel telemetry systems have been
666   successfully used in small animals (Greenwald et al. 2011; Harrison et al. 2011; Sodagar et
667   al. 2007; Szuts et al. 2011) and may be the only solution for specific applications (Yartsev
668   and Ulanovsky 2013), multiplexing and ultraflexibe cables allows much higher bandwidth,
669   higher channel counts and lower noise. The power source required for telemetry adds
670   additional weight and limit the duration of the experiments, especially in mice.

671

672   Computation in brain circuits is performed by numerous specialized neurons. Identification
673   and manipulation of specific neuron types in the behaving animal has recently become

23

674   possible with optogenetics (Boyden et al. 2005), combined with ever-increasing specificity

675   of neuron labeling, mostly in mice (Madisen et al. 2012; Taniguchi et al. 2011). Therefore,

676   perhaps the most important new direction should be the development of combined

677   techniques that allow precise delivery of light locally to the simultaneously recorded

678   neurons. Experiments have shown that as low as 5-15 µW of light is sufficient to activate

679   ChR2-expressing neurons in vivo (Stark et al. 2012). However, construction and use of

680   silicon probe devices with etched optical fibers that allow precise local delivery of light

681   energy is currently done manually and only few laboratories have the capability to use such

682   methods routinely (Anikeeva et al. 2012; Royer et al. 2010; Royer et al. 2012; Stark et al.

683   2012). To bridge the gap between optogenetics and large-scale recording of neurons, there

684   are at least two possible viable solutions. The first one is adding optical waveguides

685   integrated into the shanks of the silicon probe and coupling the back end of the waveguides

686   to lasers, LEDs or laser diodes (Stark et al. 2012; Wu et al. 2013; Zorzos et al. 2010). The

687   second option is integrating neuron-size LED sources mixed with the recording sites on the

688   silicon probe (Kim et al. 2013). Either configuration will offer unmatched spatial precision

689   and capability of targeted perturbation and recording from specified neuron types.

690   Integration of optical stimulation, large-scale recording and on-stage multiplexing will

691   facilitate the dissemination and use such tools in a large number of laboratories for the

692   investigation of multiple circuits and their behavior-dependent interactions in freely

693   moving small rodents for testing hypotheses of neural networks and brain function.

694

695 **Figure legends**

696 **Figure 1.** System overview. **(A)** High channel count (256 sites) silicon probe connected to

697 a printed circuit board via a flexible polyimide ribbon cable. The printed circuit board

698 contains 8 separate 32-channel signal multiplexers (4 on each side) and accessory circuit

699 elements. **(B)**. A simulated headstage input signal illustrating a spike waveform on one of

700 the 32 channels, and various levels of DC on the remaining 31 channels (1 ms). **(C)** Time-

701 shared multiplexed signal transmitting the 32 channels shown in b. **(D)** Circuit schematics

702 and working principle of the multiplexer and a zoomed segment of the time epoch shown

703 by rectangle in c. The multiplexer chip receives the input signals and is driven by both the

704 main microcontroller's clock signal and the complementary clock bits generated by the

705 clock divider. The horizontal line separates circuits contained in the head stage and the

706 main box. Middle part: zoomed segment of the multiplexed signal shown in b. The reset

707 line resets the clock bits to '00000' after every 32 steps to ensure the proper channel order.

708 The trigger signal is timed to sample the 'tail' of each transmitted signal snippet (marked

709 by black triangles). The two large steps (red) correspond to the two digital samples at the

710 trough of the spike waveform on input channel 3. Right part: Numeric representation of the

711 analog-to-digital converted multiplexed line (readout from the A/D card), and its

712 demultiplexed form after the software reconstruction of the digitized samples.

713

714 **Figure 2.** Surgery details of probe implantation. **(A)** and **(B)**, skull coordinates for

715 implantation of two 256-site probes into the same **(A)** or two hemispheres **(B)**. The

716 orientation of the probe shanks is indicated by pink lines, next to the probe drives. Black

717 dots, watch screws. GND, ground. REF, reference electrode. **(C)** During probe implantation

718 the probe and the PC board are rigidly connected by brass rods and the assembly is held by

719 an alligator clip. The probe is fixed to the drive and connected to the PC board by a flexible

720 polyimide cable. **(D)** The head stage after implantation. The output connector,

721 accelerometer and the copper wire mesh shield are marked by arrows. **(E)**. Details of the

722 probe shanks after they penetrated the brain. A, anterior; P, posterior direction. Bottom, top

723 view of the implanted drives. **(F)**. Rat equipped with two 256-site probes during maze

724 exploration connected to the equipment via an ultra-flexible cable (yellow).

725 **Figure 3.** Head stage multiplexers. **(A)** and **(B)** 32 and 64-channel multiplexers with high

726 density Omnetics connectors. **(C)** 64-site probe bonded to a 64-channel multiplexer. **(D)**

727 Circuit schematics representing the electrical components and wiring scheme of the 32

728 channel multiplexer. Top: wiring diagram of the INTAN RHA-2132 multiplexer chips and

729 the high-density Omnetics connector for electrode interfacing. The cutoff frequencies of the

730 low and highpass filters are set with the three resistors on the left. Bottom: Supplementary

731 electronics to provide clock bits and buffer the signal. Top row (left-to-right): 9-pin

732 Omnetics connector interfaces with the main box; high-speed dual buffer operational

733 amplifier. Bottom row: synchronous clock divider chip; external LED power port for

734 position tracking; clock inverter chip with Schmitt trigger; decoupling capacitor.

735

736 **Figure 4.** Demultiplexer circuit. **(A)** Working principle of the real time demultiplexer. The

737 clock signal from the main box (Fig. 1) is successively halved 4 times to produce 4

738 subsequent clock bits (blue trace, Bc1..5). A clockbit-mask pattern set by the user interface

739 (Bm1..5, red traces) is pairwise-compared (XNORed) with the clock bits, and the results

740 are logically ANDed. The output of this logical operation is the trigger (pink trace) which

741 switches the sample-and-hold circuit so that when the clock bits match the preset mask the

742 circuit works as a relay ($1/32^{th}$ of the running cycle); otherwise it holds the last sampled

743 voltage ($31/32^{th}$ of the running cycle). The output of the sample-and-hold circuit is shown

744 as red and blue lines for the sampling and holding periods, respectively. The example

745 demultiplexes channel 2. The demultiplexed signal trace is low-pass filtered to remove the

746 step functions, and optionally high-pass filtered at 500 Hz to separate unit firing from the

747 LFP. **(B)** Temporal delay of the demultiplexing process. Red trace: original input

748 waveform; blue trace: output of the sample and hold circuit; green trace: low-pass filtered

749 signal at the output of the demultiplexer. **(C)** Signal transmission characteristics of the

750 demultiplexer for a large-amplitude step function. Red trace: original input signal; upper

751 green trace: demultiplexed waveform; lower green trace: demultiplexed signal on an

752 adjacent channel in the multiplexed sequence. Note the different amplitude scales for the

753 traces. **(D)** Single trace examples of a demultiplexed unit. The upper two traces represents

754 two waveforms representing two distinct projections of the spike onto two adjacent

755 recording sites of the probe. The bottom trace shows the signal recorded on neighboring

756 channel in the multiplexed stream. (E) Spike-triggered average waveforms of the neuron

757 shown on panel (**D**). Note the lack of crosstalk in both the temporal (incomplete signal level

758 settling during multiplexing or demultiplexing, third trace) and spatial (crosstalk across

759 leads, fourth trace) domain.

760

761 **Figure 5.** Electroanatomy of the hippocampus. (**A**) Distribution of high frequency power

762 (300±10 Hz) on each of the 256 sites of the silicon probe. The 32 x 8 color matrix is a

763 representation of the 256-site probe shown in Fig. 1A. Each rectangle represents a 300 μm

764 (intershank distance) by 50 μm (vertical intersite distance) area to mimic the 2-dimensional

765 geometry of the probe coverage. Clustered neurons, assigned to the largest amplitude

766 recording sites, are superimposed on the power map. (**B**) Coherence maps of gamma

767 activity (30-90 Hz). The ten example sites (black dots) served as reference sites and

768 coherence was calculated between the reference site and the remaining 255 locations for a

769 one second long recording segment (Fig. 7). Middle, composite figure of the combined

770 coherence maps (see also Fig. 7). (**C**). Two-dimensional combined map of gamma

771 coherence and high frequency power distribution. Right, coastline map of layer-specific

772 coherence contours. (**D**) Histological reconstruction of the recording tracks (arrows). The

773 shifting of the tracks in the neocortex is due to a slight displacement of the

774 neocortex/corpus callosum relative to the hippocampus during the tissue sectioning process.

775 Right, physiology-based map superimposed on the recording tracks.

776

777 **Figure 6.** Layer-specific LFP power distribution of various frequency bands in the

778 hippocampus. The arrangement of each panel is the same as Fig. 3A. Each panel is showing

779 the power map of the same representative, one second-long recording segment containing

780 sharp-wave ripples. For details on filtering, see MATERIALS AND METHODS.

781

782 **Figure 7.** Coherence based clustering of electrode sites. (**A**) Cross-coherence-matrix of

783 the recorded 256 channels calculated from a randomly selected 1-sec long recording

784 segment. **(B)** and **(C)** Evolution of coherence clusters during clustering procedure. Initially

785 (T=1), electrode sites, represented by rectangles, distributed randomly among 10 clusters

786 denoted by different colors of the rectangles. T denotes the number of algorithmic steps.

787 During each step the algorithm examines whether reassignment of one randomly chosen

788 electrode site into another randomly chosen cluster would increase the clusters mean

789 coherence or not. If it increases the cluster's mean coherence, the site is merged into the

790 cluster. During the iterative reassignments clusters emerge and stabilize. Stability is shown

791 by the negligible changes between 10000 and 40000 iterations. Panel B represents the

792 clustering for a sleep session (sharp wave event), while panel **c** is created from a random

793 sample during exploratory behavior (theta).

794

795 **Figure 8.** Electroanatomy of the neocortex (**A**) Combined coherence map of gamma

796 activity (30-90 Hz), as in Fig. 5B. Each site served as a reference and coherence was

797 calculated between the reference site and the remaining 255 locations. The resulting

798 combined map is superimposed on the histologically reconstructed tracks in the

799 sensorimotor cortex. Note reliable separation of layer IV, superficial and deep layers and

800 the lack of a 'layer IV' coherence band in the adjacent motor cortex (shanks 6 to 8). (**B**)

801 300 ms long raw signal traces of a shank spanning across multiple layers of the cortex,

802 showing spike activity of multiple neurons. (**C**) Relationship between the activity patterns

803 of multiple neurons and the local field potential during a sleep spindle episode. The

804 recording site of the LFP trace in marked by * on the top of the panel in **A**. Figure is a

805 representative sample for illustration purposes only.

806

807 **Figure 9.** Characterization of single units. (**A**) Orientation of two probes placed in the same

808 hippocampus in the transveral (T) and longitudinal (L) axes (see also Fig. 2A). Histological

809 reconstruction of the recording probe shanks with superimposed traces of a sharp wave

810 ripple event (300 msec). The tissue slices were cut parallel with the probe shanks, i.e.,

811 perpendicular and parallel with the longitudinal axis of the hippocampus. (**B**)

812 Characterization of 4 different units recorded from the sites marked by the red arrows. First

813 row of each panel shows: (1) Two-msec traces of a hippocampal single unit recorded from

814 multiple sites of the shank. (2) Classification of unit clusters, recorded in a single session,

815   on the basis of their trough-to-peak duration versus spike width at 20% of the trough

816   magnitude. The relevant unit is indicated by a red dot. (3) Autocorrelogram and burstiness

817   index, determined as the ratio of spikes at <8 msec intervals divided by all spikes (Mizuseki

818   et al. 2009) and (4) interspike interval (ISI) histogram (log scale). Second raw: Cross-

819   correlation between LFP and unit firing, showing separately for theta (4-12 Hz), gamma

820   (30-90 Hz) and sharp wave-ripple (SWR; 120-250 Hz). Preferred phase of firing is also

821   shown numerically. Phase zero corresponds to through. Last panel, SWR-related firing of

822   the unit. The duration of the SWR is normalized. The modulation index (MI), defined by

823   difference/sum of the firing rate during and outside ripples, is shown above the panel. Third

824   row: Position-dependent firing rates ('place cell' activity) during left and right journeys in

825   the maze and corresponding spike-phase relationship to position within the largest place

826   field (red lines).

827

828   **Figure 10.** Comparison of single-unit isolation metrics. Each measure is shown for six

829   different recording conditions (probe, structure, species) **(A)** and **(C)** Mahalanobis distance

830   of isolated spike clusters in high dimensional feature space. **(B)** and **(D)** Contamination of

831   isolated single-unit clusters, calculated as the ratio of spikes occurring within (2 ms) and

832   after (20 ms) the refractory period of the given neuron. Medians and the interquartile ranges

833   are shown. N denotes the number of neurons fulfilling the inclusion criteria.

834   Panels **A, B** and **C, D** display the same dataset using permissive and conservative inclusion

835   criteria, respectively. Abbreviations: Hip: hippocampus; Cx: cortex; 2x256: two 256

836   channel silicon probe with multiplexing headstage; 64: Buz64-type silicon probe with 20

837   μm inter-site distance with multiplexing headstage; 64Sp: Buz64Sp-type 6 shanks silicon

838   probe, with 20 μm inter-site distance equipped with an optical fiber on each shank,

839   recorded by a non-multiplexing headstage and amplifier.

840

841   **Figure 11.** Partial circuit reconstruction from physiological interactions. (**A**) Identification

842   of monosynaptic connections. Only pyramidal-interneuron connections are shown.

843   Autocorrelogram of the reference (presynaptic) neuron (pre), referred (postsynaptic) neuron

844   (post) and cross-correlogram (CCG) between the neuron pair. Short-latency (<1 ms) narrow

845   peak (arrow) identifies the reference cell as a putative excitatory (pyramidal) neuron. Blue

846   line, mean of time-jittered spikes; red line, point wise comparison (P < 0.01); magenta line,

847   global comparison (P < 0.01; for explanation, see Methods; ref Fujisawa et al., 2008). (**B**)

848   Same as in (**A**) from another pair with members recorded from the CA3 and CA1 regions.

849   (**C**) Cross-correlogram matrix based on 26406 simultaneously recorded neuron pairs (n =

850   163 neurons) in a single session. Red pixel, monosynaptic connection (based on significant

851   short-latency peaks) with reference neuron as putative pyramidal cell (n = 127). White

852   lines, separation of neurons recorded by probe 1 and probe 2. Numbers identify the

853   recording shanks. Cross-correlograms shown in **A** and **B** are circled. (**D**) Circuit diagram

854   reconstructed from monosynaptic connections (for shank orientation, see Fig. 2). Red

855   triangles, excitatory neurons. Blue circles, putative inhibitory interneurons. Gray squares,

856   unidentified neurons. Local and CA3-CA1 connections (as shown in **A** and **B**) are

857   highlighted by yellow. Note convergence of multiple pyramidal cells on target

858   interneurons. Figure is a representative sample for illustration purposes only.

859

860   **Figure 12.** Spikes are embedded in unique and spatially distributed LFP. Spike-triggered

861   averages of the LFP in the hippocampus during slow-wave sleep (top panel) and

862   exploration (bottom panel). During sleep, spikes were sampled during sharp wave-ripples

863   (SWR); during exploration (theta), spikes of the same neuron were sampled while the rat

864   ran on a linear track for a water reward. Recordings were made by two eight-shank (300

865   μm intershank distance), 256-site silicon probes. The LFP was smoothed and interpolated

866   both within and across shanks. The LFP was triggered by the spikes of a pyramidal neuron

867   in CA1 pyramidal layer (pyr; shown by a star). Both frame sequences show four, 50 μs

868   snapshot of the LFP map before (-3 ms to -1 ms) and at the time of the spike occurrence (0

869   ms). The two images of each frame are showing the activities on the two probes (as shown

870   in Fig. 9). Note that during sleep (top panel), activity arises (negative wave, hot colours) in

871   CA3 and invades the CA1 stratum radiatum (rad). During exploration (bottom panel), the

872   spike is associated with synaptic activity mainly in the stratum lacunosum-moleculare (lm;

873   shown by an arrow) following by the radiatum layer (rad; double arrow), indicating a

874   combination of entorhinal cortex and CA3 input activation.. The LFP map changes

875   characteristically with time (see Supplemental Movie 1). ori, oriens layer; gc, granule cell

876   layer; hil, hilus.

877

878   **Figure 13.** Unit and LFP recordings from the mouse. (**A**) Chronic recordings from a mouse

879   using an 8-shank 64-site silicon probe. 100 msec epochs from each shank are shown. Inset:

880   headstage with silicon probe, microdrive and 64-channel signal multiplexer, surrounded by

881   copper mesh shielding. The freely moving mouse is connected to the equipment by an

882   ultra-flexible cable. (**B**) Two 4-shank, 32-site probes were placed in the nucleus accumbens

883   (top shanks 1-4) and ventral tegmental area (VTA; bottom shanks 1-4) in a TH-Cre;Ai32

884   mouse, expressing ChR2 in tyrosine hydroxylase-expressing neurons. One of the shanks in

885   the VTA also contained an optical fiber for light delivery (Stark et al. 2012). Note VTA

886   neuronal responses to 472 nm (bottom red trace) laser light stimulation.

893 **Competing financial interests**
894 Antal Berenyi is the founder of Amplipex Ltd., Szeged, Hungary, which manufactures
895 signal-multiplexed head stages and demultiplexing systems. The other authors declare the
896 absence of any commercial or financial relationships that could be construed as a potential
897 conflict of interest.

898

899 **Author contribution:** AB, AL, TDH and GB designed and developed the silicon probe and
900 the electronics; AB and GB designed experiments; AB, AJN, JL, SF, ES and LR conducted
901 experiments; ZS, AB and GB designed and performed analyses; AB and GB wrote the
902 paper with input from other authors.

A — (inset) Schematic of probe placement showing T and L shanks with electrode arrays positioned in hippocampus.

T — Local field potential traces (white) overlaid on color-coded spectrogram. C marks a sharp-wave ripple.

L — Local field potential traces (white) overlaid on color-coded spectrogram. B marks a burst event.
